Vegetation and Substrate on Aeolian Landscapes in the Colorado River Corridor, Cataract Canyon, Utah

By Amy E. Draut¹ and Elizabeth R. Gillette²

Abstract

Vegetation and substrate data presented in this report characterize ground cover on aeolian landscapes of the Colorado River corridor through Cataract Canyon, Utah, in Canyonlands National Park. The 27-km-long Cataract Canyon reach has undergone less anthropogenic alteration than other reaches of the mainstem Colorado River. Characterizing ecosystem parameters there provides a basis against which to evaluate future changes, such as those that could result from the further spread of nonnative plant species or increased visitor use. Upstream dams have less effect on the hydrology and sediment supply in Cataract Canyon compared with downstream reaches in Grand Canyon National Park. For this reason, comparison of these vegetation and substrate measurements with similar data from aeolian landscapes of Grand Canyon will help to resolve the effects of Glen Canyon Dam operations on the Colorado River corridor ecosystem.

Introduction

Most areas of the Colorado River corridor, in the southwestern United States, are affected by human-caused alteration, whether from changes in river flow and sediment supply caused by upstream dams, from introduced plant and animal species, or from land use in the watershed that includes

¹ U.S. Geological Survey Pacific Coastal and Marine Science Center, Santa Cruz, CA 95060

² 2 Thissell Rd., Ossipee, NH 03864

agricultural and rangeland practices. The 27-km reach of the Colorado River corridor through Cataract Canyon, Utah (fig. 1), represents the least altered region along the mainstem Colorado River below its confluence with the major Green River tributary. Because its hydrology and sediment supply are less affected by upstream dams than are any reaches of the Colorado River farther downstream, and because the immediately surrounding watershed is nearly undeveloped as part of Canyonlands National Park, Cataract Canyon provides an opportunity to study natural resources in an ecosystem less disturbed than in many other parts of the Colorado River corridor. This field study quantified ground cover (vegetation and substrate) on landscapes of Cataract Canyon that are characterized by aeolian (wind-blown) sand.

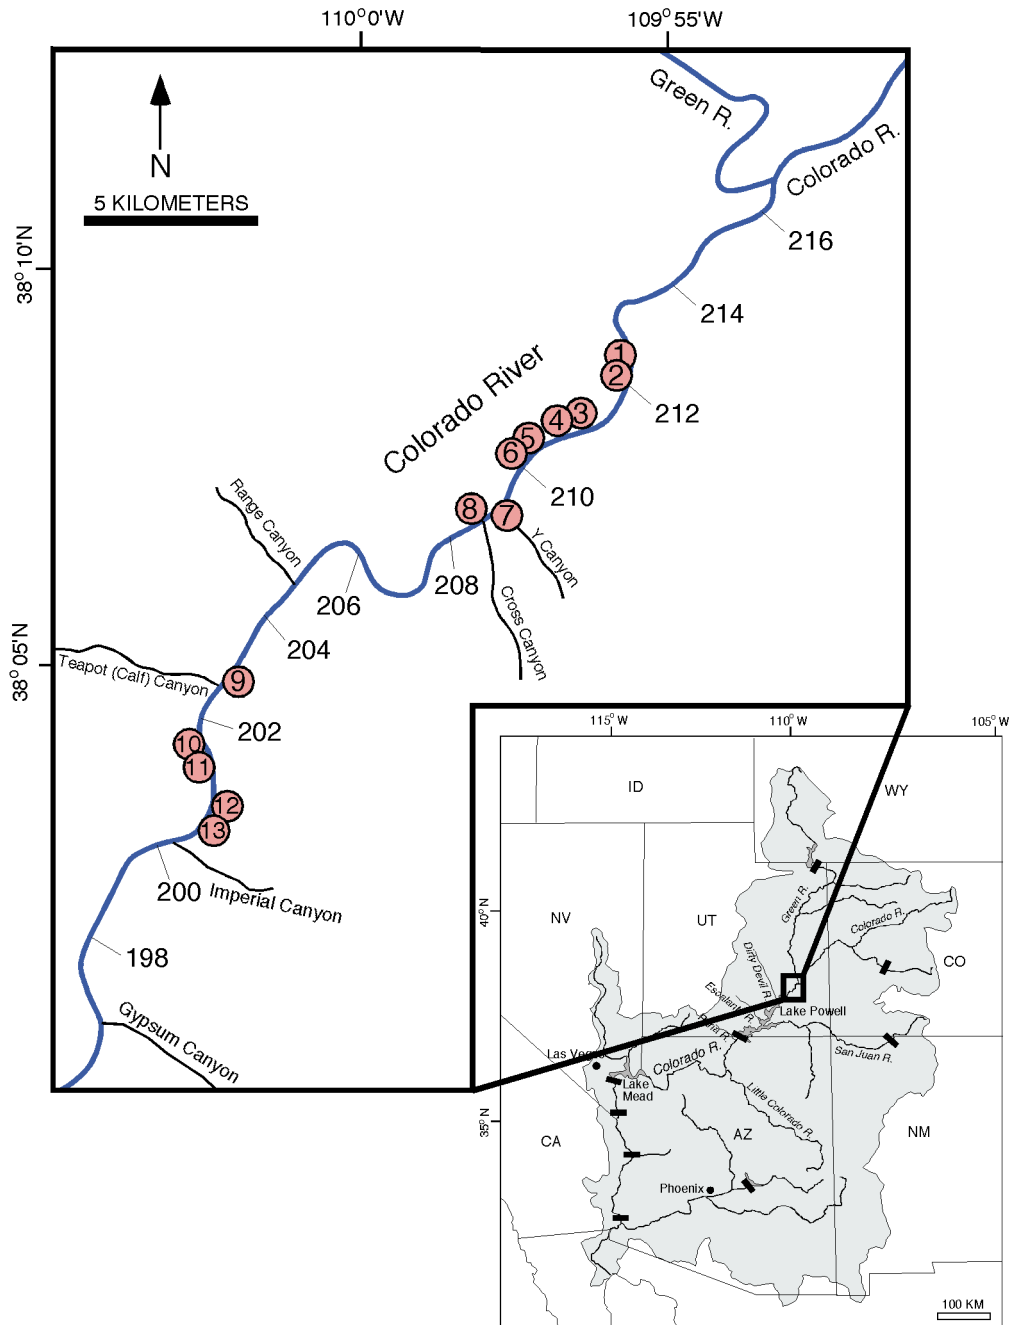

Figure 1. Study sites (numbered circles) in the Colorado River corridor through Cataract Canyon, Utah. Site descriptions are given in table 1. River miles of Belknap and others (2008) are shown. Inset map shows Cataract Canyon (box) in the context of the Colorado River basin (shaded region). Major dams of the Colorado River and its tributaries are shown as black bars on the inset map.

Project Objectives

The objective of this field study was to measure vegetation and substrate properties in aeolian dune fields within the Colorado River corridor through Cataract Canyon, Canyonlands National Park. Vegetative cover, native and nonnative species assemblages, and substrate composition including biologic crust extent are described in this report to further the ecosystem-monitoring efforts undertaken by Canyonlands National Park. These data will also be compared, in a separate publication, with ground-cover measurements made on aeolian landscapes of the Colorado River corridor in Grand Canyon National Park, a reach of the river affected substantially by flow regulation and sediment-supply limitations owing to Glen Canyon Dam operations.

This work in Cataract Canyon, upstream of Glen Canyon Dam and its reservoir, Lake Powell, constitutes part of a larger study of the effects of Glen Canyon Dam on the Colorado River corridor. Previous studies have shown that Glen Canyon Dam operations substantially reduced the size and number of fluvial sand deposits in Grand Canyon (Kearsley and others, 1994; Rubin and others, 2002; Wright and others, 2005; Hazel and others, 2006). Because fluvial sandbars are the primary source for sand that moves inland by wind and forms aeolian dune fields, the loss of fluvial sand, in turn, can reduce the supply of wind-blown sediment to aeolian dune fields downwind (Neal and others, 2000; Draut and Rubin, 2008; Draut and others, 2008, 2010) with possible consequences for ecosystems in those aeolian landscapes. To assess the degree to which sediment-supply limitation in Grand Canyon has affected conditions in aeolian landscapes there, it will therefore be informative to compare vegetation and substrate in aeolian dunes of Grand Canyon with those of Cataract Canyon, where hydrology and sediment supply more closely resemble natural conditions (see, for example, an earlier comparative geomorphic study by Thompson and Potochnik, 2000).

Methods

This study focused on the Cataract Canyon reach of the Colorado River corridor in Canyonlands National Park, between the confluence of the Green and Colorado Rivers and the recent upstream extent of Lake Powell in the area of Imperial Canyon (fig. 1). Vegetation cover (percent cover and vegetation type) and substrate were measured at 13 sites during July 2010. Study sites were chosen within landscapes dominated by aeolian geomorphology, above and within 100 m of the highest elevation of recent fluvial sand deposition. The peak stage of the spring flood in June 2010 (1,530 m³/s) was readily identifiable by the presence of driftwood, vegetation debris in wrack lines, and sandbar morphology that commonly formed separation and reattachment bars associated with eddies (Schmidt, 1990). On the basis of aeolian landforms (sand dunes, coppice dunes, and sand shadows behind rocks and vegetation), erosion, transport, and deposition by wind appeared to have been the dominant sedimentary processes recently affecting the study sites. The source of aeolian sediment at the study sites was inferred to have been a combination of new sand recently transported inland from spring flood deposits situated at lower elevation and upwind of the sites and wind reworking of sediment from older, larger flood deposits that underlie the sites (known from the presence of old driftwood logs and flood debris inland of most study sites).

Table 1 lists site numbers, names, locations, and descriptions. At Sites 1, 3, 5, and 12, ground cover appeared to be affected somewhat by camping activity, such as the presence of tent sites (Sites 1, 3, and 5) or a trail (Site 12). Sites 3 and 4 were established in the same dune field, one (Site 3) in an area affected by camp activity and the other (Site 4) apparently unaffected. Sites 5 and 6, similarly, represent camp and noncamp areas within one dune field. Although areas affected by camping activity cannot be

considered to have entirely natural conditions, they were included in this study in order to represent the range of ground cover in Cataract Canyon's aeolian landscapes as completely as possible.

Vegetation and substrate were measured at each site by establishing a layout of circles and linear transects referred to here as a "pod." As shown in figure 2, each pod consisted of two orthogonal transects marked out with a tape reel (one oriented upstream-to-downstream and the other oriented inland-to-riverward) and five circles outlined in the sand (one in the center of the pod and one at the end of each of the four transects). At study sites within small dune fields, the pods used transects 20 m long, whereas in larger dune fields the pods used transects 40 m long (table 1). For both the smaller (20 x 20 m) and larger (40 x 40 m) pod size, the five circles were always the same size, having a 3-m radius (fig. 2).

Figure 2. Scale diagram of "pod" configuration used to map vegetation and substrate in Cataract Canyon. Two transects of length 20 m and five circles of radius 3 m were used in small dune fields (as shown here). In study

sites with larger dune fields, the pod configuration included two transects of length 40 m and five circles of radius 3 m.

Along each of the transects within a pod, we measured the lengths of all gaps where the measuring tape crossed bare, open sand without rocks, biologic crust, leaf litter, or overhanging plant canopy. This method was modified from Herrick and others (2005), using their criteria to define plant canopy gaps, as a means to measure the spacing and abundance of roughness elements, vegetation, and patches of biologic crust that affect aeolian sediment mobility (Ash and Wasson, 1983; Buckley, 1987; Leys and Eldridge, 1998; Belnap, 2003; Goossens, 2004). The proportion of bare, open sand in the dune field can thus be estimated by adding all of the measured gap lengths from each transect to compile a cumulative gap length measurement and representing that total gap length as a percentage of the total transect length.

Within each of the five circles per pod, we measured the proportion of space occupied by vegetation (categorized at the species level wherever possible) and various types of substrate in which vegetation was growing. Substrate was considered in four categories: open sand, biologic soil crust, leaf litter (including driftwood, at some sites), and rock (fig. 3). We did not distinguish among the different species of biologic crust known to occur in Cataract Canyon (Webb and others, 2004). To estimate percent coverage, we compared a disc of known size with the area covered by a plant, rock, patch of soil crust, or other object of interest. The disc (radius 20 cm) has an area (0.13 m^2) approximately half of one percent of the circle size studied (28.3 m^2). By holding a disc of known radius above plants or crust cover to gage their size and percent coverage, we avoided disturbing the ground surface unnecessarily as would happen from handling plants or placing measuring devices (such as plastic grids) directly on sensitive, soil-encrusted ground. Field sites were photographed, transect orientations were measured

with a compass, and recent dominant wind directions were estimated by using compass measurements of dune slipface and sand-shadow orientations (table 1). All equipment was removed when the work was completed at each site.

Figure 3. Measuring vegetation and substrate properties on an aeolian landscape in Cataract Canyon (Site 13), summer 2010.

Results and Discussion

Tables 2–14 list vegetation and substrate properties measured at the 13 Cataract Canyon study sites. Vegetation was identified to species level wherever possible, using names and descriptions given by Taylor (1992), Williams (2000), and Huisinga and others (2006). In cases where species

identification was unclear, plants were identified by their family or genus, or by designation as annual or perennial grass, forb, or shrub.

Figure 4 summarizes vegetation cover. Sites where camping activity was apparent did not have substantially different vegetation coverage from study sites without camping activity (median vegetation coverage was 20.2 percent among the 4 sites with camp activity, compared with a median value of 23.1 percent for the noncamp sites and 22.4 percent for all 13 sites). The sites with camp activity had more open, bare sand than was characteristic of most noncamp study sites, judging from differences in total gap length (fig. 5). Median total gap length among the 4 sites with evidence of camp use was 78.7 percent, compared with 66.0 percent among the 9 noncamp sites and 68.8 percent for all 13 sites. Differences in the amount of open sand between sites with and without camp activity are largely attributable to differences in biologic crust coverage. As a group, the sites used as camps had less biologic crust than noncamp areas (fig. 6), with lower median values (1.53 percent for the sites with camp activity compared to 2.80 percent for sites without camp activity) and a much lower maximum extent (4.00 percent among the sites with camp activity compared to 37.4 percent among the noncamp sites; fig. 6). Notably, the site with the most biologic crust (Site 6) is only a short distance away from an area used as a camp, with the center of the Site 6 pod being 50 m inland of the recent spring high-water line near a large camp. Apart from one prominent trail (not near the study pod), visitor use apparently had not disturbed areas with abundant biologic soil crust a short distance away from the camp at Site 6. Substrate composition at all 13 study sites is shown in figure 7.

Diverse vegetation assemblages were recorded at the study sites, with most aeolian landscapes containing between 10 and 20 different species. Among the native plant varieties, perennial bunchgrasses such as rice grass (*Oryzopsis hymenoides*, also known as genus *Achnatherum* or *Stipa*) and several species of dropseed (*Sporobolus*) were common, as were *Ephedra* shrubs, wire lettuce

(*Stephanomeria pauciflora*), snakeweed (*Gutierrezia* sp.), forbs such as sand verbena (*Abronia elliptica*), dicoria (*Dicoria canescens*), and globemallow (*Sphaeralcea* sp.), and several members of the *Asteraceae/Compositae* family.

Every site contained at least one nonnative plant variety within the study pod. The three nonnative plants most commonly identified were Russian thistle (tumbleweed, *Salsola*), brome grasses (genus *Bromus*; we did not distinguish among varieties such as cheat grass, ripgut brome, and brown brome), and tamarisk trees (*Tamarix*). Each of these is able to spread rapidly and is considered an invasive plant in southwest desert ecosystems. *Salsola* and *Bromus* are especially adept at colonizing disturbed ground surfaces (D'Antonio and Vitousek, 1992; Belnap and others, 2009). Tamarisk and brome grasses were commonly associated with one another at the Cataract Canyon study sites, with the nonnative brome growing abundantly under tamarisk trees. Nearly all tamarisk had brown leaves and many tamarisk beetles (*Diorhabda elongata*), which land-management agencies introduced between 2005 and 2010 in an effort to curb the spread of tamarisk. Figures 8, 9, and 10 show the total area covered by *Salsola*, *Bromus*, and *Tamarix*, respectively, at the study sites. There do not appear to be substantial differences among sites with camp activity and those without, though the maximum coverage of *Salsola* and *Bromus* was highest at a noncamp site (Site 6). The apparently greater coverage of tamarisk at sites with camp activity (fig. 10) is likely due to both tamarisk and human visitors preferring locations near the river. The smaller number of study sites with camp activity may make it difficult to resolve other patterns in nonnative species prevalence that might exist between camp and noncamp areas. Figure 11 illustrates the proportions of *Salsola*, *Bromus*, and *Tamarix* at each study site relative to all other types of vegetation. In several places those plant varieties account for a substantial proportion of the vegetation community; notably, at Sites 3, 5, and 6, invasive *Salsola*, *Bromus*, and *Tamarix* together make up well over half of the total vegetation (fig. 11).

Figure 4. Box-and-whisker plots showing total area of vegetation cover, in percent, for the 4 study sites affected by camping activity (Sites 1, 3, 5, and 12), the 9 noncamp study sites, and all 13 sites combined. Length of each box spans the interquartile range (first quartile to third quartile) of the data; horizontal line through each box represents the median value. Circles mark outlier data points (those more than 1.5 times the interquartile range). Whiskers mark highest and lowest non-outlier data points.

Figure 5. Box-and-whisker plots showing total gap length, as a percent of total transect length, for the 4 study sites affected by camping activity (Sites 1, 3, 5, and 12), the 9 noncamp study sites, and all 13 sites combined.

Figure 6. Box-and-whisker plots showing biologic soil crust abundance, as a percent of total substrate, for the 4 study sites affected by camping activity (Sites 1, 3, 5, and 12), the 9 noncamp study sites, and all 13 sites combined.

Figure 7. Substrate composition at each of the 13 study sites. Site numbers are listed below columns.

Figure 8. Box-and-whisker plots showing coverage of invasive Russian thistle (*Salsola* sp.) at the 4 study sites affected by camping activity (Sites 1, 3, 5, and 12), the 9 noncamp study sites, and all 13 sites combined.

Figure 9. Box-and-whisker plots showing coverage of invasive brome grasses (*Bromus* sp.) at the 4 study sites affected by camping activity (Sites 1, 3, 5, and 12), the 9 noncamp study sites, and all 13 sites combined.

Figure 10. Box-and-whisker plots showing coverage of invasive tamarisk (*Tamarix* sp.) at the 4 study sites affected by camping activity (Sites 1, 3, 5, and 12), the 9 noncamp study sites, and all 13 sites combined.

Figure 11. Vegetation composition, in percent areal coverage, at each of the 13 study sites, identifying the proportions of three prominent invasive plant types (*Tamarix*, *Bromus*, and *Salsola*).

Conclusions

Vegetation and substrate data presented here characterize ground cover on aeolian landscapes of the Colorado River corridor through Cataract Canyon, Utah. Some changes to the natural ecosystem likely have resulted from human camping use, notably the lower abundance of biologic soil crust and correspondingly more open, bare sand in dune fields that sustain some camp activity compared to those that do not. Nonnative vegetation was present among the plant communities at each of the 13 study sites. Invasive *Salsola*, *Bromus*, and *Tamarix* now compose a substantial proportion of the plant community in Cataract Canyon's aeolian landscapes.

These data can form a basis against which to evaluate future changes in the Cataract Canyon ecosystem, the least disturbed region of the Colorado River corridor below the confluence with its largest tributary, the Green River. Upstream dams have less effect on the hydrology and sediment supply in Cataract Canyon compared to downstream reaches in Grand Canyon National Park. For this reason, comparison of these vegetation and substrate measurements with similar data from aeolian landscapes of Grand Canyon will help to resolve the effects of Glen Canyon Dam operations on the Colorado River corridor ecosystem.

Acknowledgments

This work was conducted under National Park Service Research and Collecting permit CANY-2010-SCI-0003. The authors thank John Weisheit for providing logistical field support and sharing his greatly detailed knowledge of Cataract Canyon's natural and human history. R.L. Reynolds and C.D. Storlazzi provided constructive review comments that improved this report.
